Abstract Authors of socioecological models propose that food distribution affects female social relationships in that clumped food resources, such as fruit, result in strong dominance hierarchies and favor coalition formation with female relatives. A number of Old World monkey species have been used to test predictions of the socioecological models. However, arboreal forest-living Old World monkeys have been understudied in this regard, and it is legitimate to ask whether predominantly arboreal primates living in tropical forests exhibit similar or different patterns of behavior. Therefore, the goal of our study was to investigate female dominance relationships in relation to food in gray-cheeked mangabeys (*Lophocebus albigena*). Since gray-cheeked mangabeys are largely frugivorous, we predicted that females would have linear dominance hierarchies and form coalitions. In addition, recent studies suggest that long food site residence time is another important factor in eliciting competitive interactions. Therefore, we also predicted that when foods had long site residence times, higher-ranking females would be able to spend longer at the resource than lower-ranking females. Analyses showed that coalitions were rare relative to some other Old World primate species, but females had linear dominance hierarchies. We found that, contrary to expectation, fruit was not associated with more agonism and did not involve long site residence times. However, bark, a food with a long site residence time and

potentially high resource value, was associated with more agonism, and higher-ranking females were able to spend more time feeding on it than lower-ranking females. These results suggest that higher-ranking females may benefit from higher food and energy intake rates when food site residence times are long. These findings also add to accumulating evidence that food site residence time is a behavioral contributor to female dominance hierarchies in group-living species.

Introduction

Group living is often associated with feeding competition (Alexander 1974; Pulliam and Caraco 1984), the cost of which may not be evenly distributed among individuals within a group. In groups with linear dominance hierarchies, the distribution of the cost of feeding competition may be in part determined by rank, as high rank is often associated with greater feeding and foraging success and lower costs (Vehrencamp 1983). For example, in semi-free-ranging adult female American bison (*Bison bison*), dominance rank correlates with fatness and with the weight of offspring at weaning (Vervaecke et al. 2005) and in small groups of wild blackbirds (*Turdus merula*), top-ranking individuals benefit from a greater increase in foraging success than bottom-ranking individuals (Smith et al. 2001). Because of the great energetic demands of gestation and lactation, differential female reproductive success in mammals is thought to result from differential access to food (Trivers 1972). Thus, in many mammals, the study of

female social relationships has focused in particular on the association between dominance rank and feeding competition (e.g., macaques (*Macaca fascicularis*), van Schaik and van Noordwijk 1988; chamois (*Rupicapra rupicapra*), Ingold and Marbacher 1991; mountain goats (*Oreamnos americanus*), Fournier and Festa-Bianchet 1995; elephants (*Loxodonta africana*), Archie et al. 2006; chimpanzees (*Pan troglodytes*), Murray et al. 2006). In group-living primates, high rank has been linked to better foraging efficiency (Range and Noë 2002), higher food and energy intake rates (e.g., Janson 1985; Saito 1996; Vogel 2005), and longer food site residence or handling time (e.g., Isbell et al. 1998; Pruettz and Isbell 2000; Mathy and Isbell 2001; Chancellor and Isbell 2008). High rank is also often associated with greater reproductive success (Dunbar 1980; Busse 1982; van Noordwijk and van Schaik 1987; Saito 1996; Pusey et al. 1997). A majority of the research on primates has been on Old World monkeys (e.g., van Schaik and van Noordwijk 1988; Borries 1993; Isbell and Pruettz 1998; Range and Noë 2002). Previous studies have found that, in cercopithecine primates such as macaques (*Macaca* spp.), baboons (*Papio* spp.), and vervets (*Cercopithecus aethiops*), frequent agonistic interactions between females result in stable linear dominance hierarchies that are maintained through alliances of female relatives (Walters and Seyfarth 1987; Chapais 1992). Closely related females provide support against more distantly related females, and matriline of higher rank support each other in coalitions against matriline of lower rank (Seyfarth 1980; Hausfater et al. 1982; Barton and Whiten 1993; Chapais et al. 1997).

With the exception of blue monkeys (*Cercopithecus mitis*; Cords 2000, 2002), studies of female relationships in African monkeys have largely been limited to the more terrestrial species living in more open habitats, e.g., vervets, patas monkeys (*Erythrocebus patas*), and baboons (Seyfarth 1976; Byrne et al. 1989; Isbell and Pruettz 1998; Silk et al. 1999). A growing number of field studies provide evidence, however, that ecology influences female competitive relationships more than phylogeny (Mitchell et al. 1991; Isbell and Pruettz 1998; Boinski et al. 2002), and it is legitimate to ask whether predominantly arboreal primates living in tropical forests exhibit similar or different patterns of behavior. For example, dense foliage or narrow branch substrates within tree canopies could influence the rate of agonistic interactions or the coordination of coalitions. Evidence that this might be the case in tropical forests comes from a study of chacma baboons (*Papio cynocephalus ursinus*) living in a woodland habitat. Even in this woodland habitat, which likely has greater visibility than most tropical forests, reduced visibility limited the ability of higher-ranking individuals to scan or to control food patches that lower-ranking individuals occupied (Ron et al. 1996).

Authors of current socioecological models propose that food distribution affects female social relationships in that spatially clumped food resources, such as fruit, result in strong dominance hierarchies and favor coalition formation with female relatives (Wrangham 1980; van Schaik 1989; Sterck et al. 1997; Koenig and Borries 2006). In other highly frugivorous species, larger groups also travel farther per day than smaller groups, suggesting that feeding competition imposes increased costs in larger groups (Isbell 1991; Chapman et al. 1995; Janson and Goldsmith 1995). Group-adjusted daily travel distance in frugivorous primates is also typically associated with clearly defined female dominance hierarchies (Isbell 1991). There is increasing evidence, however, that another relevant characteristic of foods, at least in terms of female dominance relationships within groups, is depletion time. Foods that are depleted slowly can be clumped or widely dispersed but, more importantly, they appear to be more usurpable than foods depleted quickly because individuals spend more time at these foods, and usurpability favors agonistic interactions that allow observers to detect dominance hierarchies (Isbell et al. 1998; Isbell and Young 2002). Foods at which individuals spend a long time also most likely reflect high resource value since the amount of time spent at a resource may be an index of its value to the individual (Harcourt and Stewart 2007). Increasingly, studies are finding that larger foods (Mathy and Isbell 2001; Chancellor and Isbell 2008; Gemmill and Gould 2008) or foods with longer site residence times (Post et al. 1980; Janson 1990; Isbell et al. 1998; Pruettz and Isbell 2000) are more usurpable and elicit more aggression.

In a study of yellow baboons (*P. cynocephalus cynocephalus*), high-ranking individuals in general were found to have longer feeding bouts than low-ranking individuals. Feeding bouts of high-ranking individuals were also less likely to be aggressively interrupted, and those individuals whose bouts were interrupted most had the shortest mean feeding bout durations (Post et al. 1980). In another study on vervets, higher rank was correlated with longer mean time spent at food sites (Isbell et al. 1999). In experiments with captive rhesus macaques (*Macaca mulatta*), foods with longer handling times elicited more aggression, and higher-ranking individuals were more likely to get those foods (Chancellor and Isbell 2008).

In this study, our goal was to extend our understanding of the ecology of female social relationships by specifically investigating the potential for a temporal characteristic of food, food site residence time, to affect female dominance relationships, in a tropical forest-dwelling and largely arboreal Old World monkey species, gray-cheeked mangabeys (*Lophocebus albigena*). Gray-cheeked mangabeys have been the subjects of numerous studies in Kibale National Park, Uganda, over many years (e.g., Waser 1977;

Freeland 1979; Olupot et al. 1998; Lambert et al. 2004). Like most open-country cercopithecines, gray-cheeked mangabeys live in multimale/multifemale social groups. Females make up the stable core of the group whereas males disperse (Waser 1975; Olupot and Waser 2001). Although ecological and socioecological studies on feeding, ranging, and activity patterns have been conducted on gray-cheeked mangabeys (e.g., Waser 1978; Freeland 1979; Olupot et al. 1998; Olupot and Waser 2001), virtually nothing is known about competitive relationships between females within groups.

Mangabeys are predominantly frugivorous (Waser 1977), and larger groups of mangabeys (those over 15 individuals) travel farther per day than smaller groups (Waser 1977). Since fruits are often considered clumped and a clumped food distribution has often been assumed to be the underlying ecological cause of both adjustments of daily travel distance based on group size and obvious dominance relationships among females, we predicted the following in gray-cheeked mangabeys:

1. Females have agonistic interactions frequent enough for observers to detect dominance hierarchies.
2. Females form coalitions, a prediction of socioecological models when females have linear dominance hierarchies.

However, since we are also concerned here with usurpability and fruits are often large, with long residence times (at least relative to arthropods), we predicted that:

3. Food sites of different food types have different residence times, depending on resource value and consumption or processing time, e.g., fruit sites have longer residence times than leaf sites, and leaf sites have longer residence times than arthropod sites.
4. Food sites with long residence times are more associated with aggression than food sites with short residence times.
5. Higher-ranking females feed longer at food sites with longer residence times.

Methods

Study site and subjects

We conducted this project in the Kanyawara study area of the semilogged moist evergreen forest of Kibale National Park (766 km²), Uganda (0° 34' N, 30° 21' W), located near the foothills of the Rwenzori Mountains (Waser and Floody 1974; Chapman et al. 1997). The area has a mean annual rainfall of 1,778 mm (1990–1998) and a mean daily minimum and maximum temperature of

15.5°C and 23.7°C, respectively (Chapman and Chapman 2000).

We collected data on five study groups (BT1, BT2, LC, CC, MK) that have been followed at least once a month since the mid-1990s. We chose the groups for their home range locations, number of females, and the relative ease with which we could follow females and identify them by their natural markings. All groups were equally well habituated, allowing observations as close as 2 m. Since gray-cheeked mangabeys are primarily arboreal, all groups spent most of their time in the canopy but all groups occasionally came to the ground to forage, drink, travel, etc. Group sizes ranged between ten and 21 individuals and consisted of between four and seven adult females, one and nine adult males, and three and ten immature individuals (group sizes: BT1=10–16; BT2=12–15; LC=17–21; CC = 14–17; MK=12–16). The mangabeys at Kibale occupy a variety of habitats, from undisturbed to lightly and heavily disturbed forest (Skorupa 1988). The study groups lived primarily within lightly to moderately logged forest except for CC, which ranged primarily in unlogged forest. Home ranges were between 54 and 87 ha (BT1=66; BT2=79; LC=87; CC=61; MK=54), estimated by counting the number of 50×50-m quadrats entered at least once (e.g., Isbell 1983) from global positioning system recordings of group movements every half-hour during sampling days (avg 3 days per group per month).

Data collection

We collected data between January 2004 and August 2005. We could identify all adult and subadult females individually by July 2004. Adult females were those exhibiting visible sexual swellings and subadult females were similar size to adults that began to exhibit visible sexual swellings during the study period. In each group, we began systematic data collection when we could identify all adult and subadult females ($N=26$; BT1=5; BT2=4; LC=7; CC=5 MK=5). We conducted an average of three all-day group follows per month on each group (mean (range): BT1=3 (2–5); BT2=3 (0–8); LC=5 (2–7); CC=3 (2–5); MK=3 (1–5)). We sampled the groups using predetermined random sampling without replacement. Since mangabeys have fairly large home ranges, if we could not find a group, we sampled another group whose location was known. We sampled each female in the group at least once for a continuous 30-min focal during each all-day group follow. Because individual females could be difficult to find, we determined the sampling order within groups by locating the first female not yet sampled during the sampling day. As soon as the female was located, we began the 30-min focal. If a female went out of view, we attempted to locate her for 20 min. If she was found again

within 5 min, we continued the sampling. If she was found after 5 min, we discounted the time while out of sight and followed her for a total of 30 focal minutes.

We collected behavioral data using a combination of focal and all occurrences sampling. We determined dominance relationships by the direction of agonistic dyadic interactions involving females, including chases (i.e., aggressively pursuing another), approach–avoids (i.e., moving away from another who is approaching), supplants (i.e., taking the place of another), physical contacts (e.g., biting, tail-pulling, pushing), and nonphysical threats (e.g., facial threats). We used only interactions in which we could determine a clear aggressor in the dominance hierarchy calculations. A coalition occurred when one female actively supported another female in an agonistic interaction with a third party. The data set consists of 532 h of focal follows of 26 females (total hour (mean hour per female): BT1=98 (20); BT2=74 (19); LC=139 (20); CC=114 (23); MK=107 (21)).

One way of assessing depletion time of food is to consider food site residence time. As per Isbell et al. (1998), we recorded food site residence time using the behavior of females during focal samples. We recorded food site residence time by noting the duration of time per food site, where we defined a food site as any spot at which an individual stopped to eat food and which was separated by other food sites by hind limb locomotion (i.e., both hind limbs had to move; an animal just turning itself or taking a step with one foot to reach for food was not counted as hind limb locomotion). Since it is unclear whether or not the food was actually depleted before the animal moved on, we amend the original term depletion time (Isbell et al. 1998) to residence time. In addition, we recorded the food items eaten at each food site. We divided food items into five general categories for analyses: fruit (fruit and seeds), arthropods, leaves, flowers, and bark (bark cambium and pith). We excluded fungi food sites (i.e., mushrooms, lichen) from analyses because they were eaten only rarely and not by all focal females or groups.

Statistical analyses

Dominance analyses included agonistic interactions from both focal and all occurrences sampling. We used a Bayesian analysis to determine female dominance hierarchies. Similar to nonparametric methods, Bayesian analysis determines the most likely rank orderings. Unlike nonparametric methods, it provides additional measures of certainty by generating the posterior probabilities of those orderings based on prior probability distributions. This makes it possible to find out if there are several plausible hierarchies with similar posterior probabilities. More traditional nonparametric methods only produce a single “best” hierarchy, with no added information about other plausible hierar-

chies. Therefore, they provide no information regarding uncertainty of the “best” hierarchy (i.e., how much better it is than the next best hierarchy; Gill 2002; Adams 2005).

We based the Bayesian models on Adams (2005) and personal communication with Adams, and they are available upon request. Adam’s model is a Bayesian version of the Bradley–Terry model (Bradley and Terry 1952). Under the Bradley–Terry model, (1) the number of wins by animal i in n contests with animal j is a binomial random variable with parameters n and p_{ij} ; and (2) the logit of p_{ij} is equal to the difference in dominance indices between the animals, $d_i - d_j$. Adams’ model uses a normal distribution centered at zero as the prior for each dominance index d .

After checking for intransitivities, we conducted analyses in WinBUGS 1.4 (Spiegelhalter et al. 2003), a software program that uses Markov chain Monte Carlo (MCMC) simulation to fit the Bayesian models (Adams 2005). The prior distribution for dominance indices was a normal distribution with mean of zero and variance chosen for each group to ensure adequate mixing of the Markov chain. We aimed at using a prior that was narrow enough for the chain to mix without narrowing so much as to constrain the posterior. Therefore, our smallest prior variance used (variance=1/0.04=25, for groups LC and MK) still provided a broad enough prior distribution to allow for adequate spread of posterior dominance indices, especially for these relatively small dominance hierarchies. For groups LC and MK, we chose a variance of 25 because when the prior had a variance >25, the Markov chain did not mix well, and we were not able to get information about the posterior. In order to test the sensitivity of the results to the priors, we ran two of the groups, CC and BT2, with both the largest (1,000) and smallest (25) prior variances used in the analyses, and found that reducing the variance to 25 did not change the most probable dominance hierarchies. For each group, we discarded the first 500 MCMC iterations (i.e., the “burn-in” portion of the Markov chain) to ensure convergence to a suitably stationary posterior distribution before drawing the 10,000 samples used to find the posterior probability of rank orderings (see also Adams 2005). We used CodaReader 1.01 (Adams 2005) to find the posterior probability of rank orderings.

For comparability with more traditional measures of dominance, we also checked the percentage of reversals and the directional consistency index (DC index), which ranges from 0 to 1 and is calculated by $(H-L)/(H+L)$, where H is the total number of agonistic interactions in the direction of higher frequency and L is the total number of agonistic interactions in the direction of lower frequency (e.g., van Hooff and Wensing 1987; Archie et al. 2006), using MatMan 1.1 (Noldus Information Technology b.v., The Netherlands).

The DC index and the percentage of reversals are particularly useful when groups are smaller than six, when tests based on the Landau linearity index (h) or de Vries's corrected linearity index (h') have diminished statistical power (Appleby 1983; Isbell and Young 2002; Archie et al. 2006). In addition, we calculated de Vrie's corrected linearity index (ranging from 0 to 1) for LC, the group in which there were enough females ($N=7$) to do the test.

To test whether rank and different food types (fruit, leaves, bark, arthropods, flowers) predicted different food site residence times, we fitted a mixed-effects linear model with random effects for group and female within group and fixed effects for rank, food type, and the interaction between rank and food type. The unit of observation was food site visited by a female during focal sampling. We log-transformed the food site residence time data because of a right-tailed skew. We used the hierarchy for each group having the largest posterior probability to assign rank.

We conducted all analyses except the dominance matrices using the software program JMP 7 (SAS Institute Inc., Cary, NC, USA). We set statistical significance at $P=0.05$ and all tests were two-tailed. Throughout the manuscript, the means and standard deviations are provided unless otherwise noted.

Results

Dominance hierarchies

During 532 focal hours, we observed a total of 301 dyadic agonistic interactions between females (BT1=70; BT2=46; LC=72; CC=48; MK=65; events per female per focal hour: BT1=0.14; BT2=0.16; LC=0.07; CC=0.08; MK=0.12). The most frequent agonistic interaction was approach-avoid (44%), followed by supplant (35%), chase (14%), physical contact (4%), and nonphysical threat (2%). Food was the target of more than half (55%) of all observed agonistic interactions.

As predicted, females in all five groups could be placed into linear dominance hierarchies using both the Bayesian analyses and the nonparametric analyses. Figure 1 shows the posterior probabilities, for the Bayesian analyses, of the most likely dominance rankings, from highest to lowest, for each group within a 95% credibility set. The posterior probabilities varied by group. For example, the posterior probability for the most likely rank ordering for the MK group was 98%, while the most likely rank ordering for the LC group was 42%. The lower probabilities in LC, in particular, may be due to fewer interactions being observed between some dyads.

For each group, the nonparametric method produced the dominance hierarchy having the largest posterior

probability under the Bayesian method. This was most likely because agonistic interactions among females were strongly unidirectional and the number of reversals was relatively low, indicating that most interactions followed the direction of the hierarchy (LC group, directional consistency index 0.97, reversals 2%; CC group, directional consistency index 0.82, reversals 9%; MK group, directional consistency index 0.88, reversals 6%; BT1 group, directional consistency index 0.96, reversals 2%; BT2 group, directional consistency index 0.83, reversals 9%). LC, the group in which there were enough females to calculate de Vrie's linearity test, showed significant linearity ($h'=0.82$, $p=0.04$).

Third-party interventions and female coalitions

During focal hours, we observed five agonistic dyadic interactions between females that led to intervention by a third party (2% of all agonistic interactions). In two cases, the third party was another female and in the other cases the third party was a juvenile female twice and a juvenile male once. Outside of focal hours, we observed only one other agonistic interaction between females that led to intervention by a third female.

Although females formed obvious linear dominance hierarchies, coalitions between females were infrequent. During focal hours, females formed 12 coalitions, including the two mentioned above. Outside of focal hours, we observed ten additional female coalitions, including the one mentioned above. Half of female coalitions (11 of 22) were directed towards adult males. Females formed coalitions most often with females within one rank distance of their own (13 of 18 coalitions (72%)). At least seven (32%) of the 22 coalitions were over food.

Food site residence time, rank, and food type

We recorded 10,525 food sites for which we had complete residence times (range 290–614 sites per female). Of those sites, over half involved fruit (52%). Arthropods were second with 30%, followed by leaves (8%), flowers (7%), and, finally, bark (3%). Overall, mean food site residence time was 66 ± 87 s.

The independent effect of food type significantly predicted food site residence time ($F_{4, 10,447}=65.93$, $P<0.0001$). The mean food site residence time for bark (150 ± 206 s), the food type with the longest residence time, was over twice that of arthropods (55 ± 60 s), the food type with the shortest residence time (Table 1). As predicted, the food types' mean residence times closely corresponded to the percentages of their food sites contested (Table 1; Fig. 2). Overall, rank did not significantly predict food site residence time ($F_{1, 37.71}=0.24$, $P=0.6$) nor did the interac-

tion between rank and food type ($F_{4, 10372}=1.84, P=0.1$). This was largely due to a poor rank effect on food site residence times for fruits, flowers, and leaves. In contrast, there was a significant positive relationship between rank and bark site residence time (Table 2). As rank increased, bark site residence time increased, so that higher-ranking females fed for longer periods at bark sites than lower-ranking females. For example, the estimate showed that a female of rank 1, on average, spent 1.5 times longer feeding at a bark site than a female of rank 7 (Fig. 3). There was also a small but significant negative relationship between

rank and arthropod site residence time (Table 2). As rank increased, arthropod site residence time decreased, so that higher-ranking females fed for shorter periods at arthropod sites than lower-ranking females. For example, the estimate showed that a female of rank 1, on average, spent only 0.88 times as long feeding at an arthropod site than a female of rank 7. In addition, there was a small, though not significant, negative relationship between rank and fruit site residence time (Table 2).

Bark cambium or pith was eaten from *Celtis africana*, *Blighia unijugata*, *Trema guineensis/orientalis*, *Linociera johnsonii*, *Pseudospondias micocarpa*, *Millettia dura*, *Macaranga schweinfurthii*, and *Prunus (Pygeum) africana*.

Table 1 The percentage of sites contested and the mean site residence time for each food item

Food item	Total no. of sites	% sites contested (95% CI)	Mean site residence time (s; 95% CI)
Fruit	5,504	1.7 (1.3, 2.0)	62 (60, 64)
Arthropods	3,177	0.9 (0.5, 1.2)	56 (53, 58)
Leaves	843	1.4 (0.6, 2.2)	80 (74, 87)
Flowers	676	2.2 (1.1, 3.4)	86 (78, 94)
Bark	325	5.5 (3.0, 8.1)	150 (127, 172)

Collectively, these trees are not rare. Enumerations conducted in 1992, for example, showed that they occurred at a density of approximately 45 stems per hectare (Chapman et al. 1997). As another way to examine the link between food site residence time and competition between females, we compared food site residence time and aggression at bark and fruit sites in *C. africana*, the most common tree species from which mangabeys ate bark cambium (49% of total bark sites recorded). In addition to its continually available bark, *C. africana* produces fruits at low levels throughout the year (Struhsaker 1997). Despite the availability of both bark and fruits, however, aggression occurred at 9.6% of bark sites but only 0.3% of fruit sites. This difference between bark and fruit in the percentage of aggression closely parallels the difference between bark and fruit in residence time: the average residence time in *C. africana* was 214 ± 124 s for bark sites vs 43 ± 15 s for fruit sites.

Discussion

Female dominance relationships

Female agonism was frequent enough in gray-cheeked mangabeys to detect linear dominance hierarchies in all five study groups. Most agonistic interactions between females were nonaggressive approach–avoids or supplants. This suggests that the females in the study groups had relatively well-established dominance hierarchies in which they could assess one another's contest ability without escalation (Parker 1974).

Both the Bayesian analyses and the nonparametric analyses revealed the same “best” rank orderings for all groups. This was most likely because agonistic interactions among females were strongly unidirectional and the number of reversals was relatively low indicating that most interactions followed the direction of the hierarchy. In spite of this, the posterior probabilities from the Bayesian analyses varied by group. In some groups, the 95% credibility set contained several hierarchies, while in other groups it contained only one or two. For example, the “best” hierarchy for LC had only a 42% posterior probability and the 95% credibility set contained six possible hierarchies, while the “best” hierarchy for MK

had a 98% posterior probability and contained only one hierarchy in the 95% credibility set. Therefore, the Bayesian analysis revealed that there is more confidence in the hierarchy of the MK females than that of the LC females. The lower probabilities in LC, in particular, may be due to fewer interactions being observed between some dyads.

Gray-cheeked mangabeys in Kibale appear to have somewhat higher agonistic rates than several populations of guenons, similar rates to two populations of macaques, and lower rates than one population of baboons, a species to which mangabeys are relatively closely related (e.g., Harris 2000; Tosi et al. 2003; Fig. 4). However, given the limitations of a small sample size (e.g., baboon populations may vary in their coalition probabilities) and different methodologies used (e.g., different studies may use different kinds of interactions), we note only that the agonistic rates of gray-cheeked mangabeys are nestled among those of other papionins, the clade to which mangabeys belong.

Third-party interventions and female coalitions

Agonistic interactions between females that led to intervention by a third party (2% of total agonistic interactions) were uncommon. In a study of yellow baboons, a closely related species (e.g., Harris 2000; Tosi et al. 2003), 4–6% of female agonistic interactions led to intervention by third parties, and 1–4% of those third parties were female (Silk et al. 2004). Coalitions between females were also infrequent, but when females did form coalitions, they formed them most often with females of similar rank to themselves, and half were directed against adult males. Despite the prediction of socioecological models of female relationships that female coalitions co-occur with clearly defined dominance hierarchies, other studies of Old World monkeys have also found coalition formation among females to be rare (blue monkeys, Cords 2002) or nonexistent (chacma baboons, Barrett et al. 1999). The infrequency of female coalitions in other well-studied cercopithecine primates suggests that they may not be as important to female intragroup feeding competition as socioecological models predict. However, Cords (2002) suggested that, even when rare, the occurrence of coalitions might still be important in influencing behavior, specifically competition for food. As

Fig. 2 The relationship between the mean food site residence time and the percentage of contested food sites per food item

socioecological models predict (Wrangham 1980; van Schaik 1989; Isbell 1991; Sterck et al. 1997), food was also the target of more than half of all observed agonistic interactions between females, and the target of at least 32% of female–female coalitions.

Food site residence time and female dominance relationships

Mangabeys are predominantly frugivorous; fruits constituted over half of their diet. Fruits are often considered

Table 2 The parameter estimates from the mixed-effects linear regression model examining the effects of rank, food type, and the interaction between the two on log-transformed food site residence time

Term	Estimate	SE	<i>t</i> ratio	Prob> <i>t</i>

Flowers×rank	0.004	0.02	0.17	0.87
Fruit×rank	0.02	0.01	1.86	0.06

The interactions between bark and rank and arthropods and rank had a significant effect on food site residence time ($N=10,525$). Negative estimates for rank and interactions with rank reflect the fact that lower values are assigned to higher-ranking females (i.e., the highest-ranking female in a group is ranked 1). The model R^2 was 0.04, and the percentage of variance explained was 0.8% for female within group, 1.0% for group, and 98.2% for residual

Fig. 3 Female rank by median bark food site residence time ($N=325$). The highest-ranking female is assigned a rank of 1 and the lowest-ranking female, 7. Squares represent the medians, and bars and whiskers represent the 25% and 75% quartiles

clumped and worth fighting over, and their clumped distribution has often been thought to be responsible for female dominance hierarchies (e.g., Wrangham 1980; van Schaik 1989). However, recent studies have found that young leaves are also often clumped (e.g., Snaith and Chapman 2005; Koenig and Borries 2006). Surprisingly, female mangabeys did not interact agonistically over fruits (or leaves) more than other food types and high-ranking females did not spend more time than lower-ranking females at food sites with fruits, flowers, or leaves. Instead, agonistic interactions occurred most predictably when females ate bark, and higher-ranking females spent more time at bark sites than lower-ranking females.

Although our goal was not to examine the spatial distribution or abundance of different food types in relation to female competition, we suggest that residence time at bark food sites was not spuriously correlated with aggression via the clumped spatial distribution or rarity of bark for three reasons. First, although bark was eaten rarely compared to fruits and leaves, it appears to be a readily available food type. The mangabeys fed on bark cambium or pith from several species of trees and the bark could be both clumped and dispersed. Although some bark trees occur at low densities in the Kanyawara area (e.g., *Premna angolensis*: one to two stems per hectare), others are relatively common (e.g., *C. africana*: up to 19 stems per hectare; Struhsaker 1975; Chapman et al. 1997; Isbell, unpublished data). Collectively, however, the tree bark from which mangabeys eat occurs at a fairly high density in Kibale. Second, the distribution of bark varies. Within a given tree, for example, bark cambium from the trunk and

Fig. 4 Agonistic rates for different populations of female Old World monkeys based on either total focal or total observation hours. See text for caveats related to the interpretation of these comparative data. Sources: (*Cercopithecus aethiops* and *Erythrocebus patas*, Isbell and

Pruetz 1998; *Cercopithecus mitis erythrarchus*, Payne et al. 2003; *Cercopithecus mitis stuhlmanni*, Cords 2000; *Lophocebus albigena*, this study; *M. fuscata*, Saito 1996; *M. fuscata yakui*, Hill and Okayasu 1995; *P. cynocephalus ursinus*, Barrett et al. 1999)

large branches is clumped relative to pith from twigs within the canopy. More importantly, however, bark within the canopy is likely to be no more clumped than fruits, the foods that we expected females to compete over most because of their presumably clumped distribution. Finally, bark is continuously available.

Bark was the food that took the longest time to consume, probably because it requires time to prepare for eating. Live bark is often ripped off the tree in strips up to a meter long and then the cambium is removed with canines (e.g., *C. africana* trees), or bark is peeled back from twigs broken off of branches and then the pith is consumed (e.g., *P. angolensis* trees; Waser 1977; Olupot 1998; RLC, personal observation). A site may also yield multiple strips or twigs, allowing an individual to feed at the site for a long period of time. Given that there was greater competition over bark than over other food types, it is not surprising that high-ranking females spent more time than lower-ranking females at food sites with bark. Being able to spend longer periods at food sites may be energetically advantageous. Bark may be high in nutrients, including protein and soluble sugars (Rogers et al. 1994). According to Waser (1977), the bark of *C. africana*, a preferred bark source for the mangabeys in Kibale, is sweet. An individual that has to leave a site earlier than she otherwise would because of aggression will likely incur extra travel and search costs before finding another appropriate site, and higher-ranking individuals, by definition, are those that dispense the most and receive the least aggression. Our results add to accumulating evidence that food site residence time is a

behavioral contributor to female dominance hierarchies (Isbell et al. 1998; Mathy and Isbell 2001; Vogel and Janson 2007; Chancellor and Isbell 2008). Similarly, in mountain gorillas (*Gorilla gorilla beringei*), dominant adult males are able to stay twice as long (8.5 min) at feeding spots than subordinate females (2.5–4.0 min; Fossey and Harcourt 1977). Being able to sit undisturbed while feeding may contribute to greater foraging efficiency or higher food and energy intake rates for high-ranking individuals.

Bark eating is a unique characteristic of mangabeys relative to other cercopithecines (*C. mitis* and *Cercopithecus ascanius*) in Kibale (Waser 1977; Lambert et al. 2004). Why do female mangabeys compete over bark? Even though bark makes up a small percentage of the mangabey diet, the evident competition over it suggests that it may be very important, perhaps as a fallback food when preferred foods are not available (Lambert et al. 2004). Bark has been argued to be an important fallback resource for gorillas (*G. gorilla gorilla*; Rogers et al. 1994), orangutans (*Pongo pygmaeus*; Knott 1998), and Barbary macaques (*Macaca sylvanus*; Menard and Qarro 1999). In mountain gorillas, aggression occurs over decaying wood (Harcourt and Stewart 2007), and it has recently been found to be a very important source of sodium in their diet (Rothman et al. 2006). Ultimately, aggression over bark sites in mangabeys may be a consequence of both long site residence times (making bark sites usurpable) and potentially high resource value (making them worth spending time on).

Interestingly, arthropods had the shortest residence times and were negatively associated with high rank. Many

arthropods can be eaten very quickly because they are small, occur as solitary individuals, or have defenses that preclude continued feeding on them (e.g., Sillén-Tullberg and Leimar 1988; Krall et al. 1999; Eisner et al. 2000; Isbell and Young 2007). All of these characteristics may make arthropods difficult to usurp. Because arthropods are difficult to usurp, low-ranking individuals may make up for nutrients lost at bark sites by feeding longer at arthropod sites. However, with a valuable but nonusurpable food resource, a high-rank advantage might involve being able to harvest the prey more efficiently, and thus reducing site residence time, rather than being able to have a long site residence time. Rank advantages in foraging efficiency occur in other species. For example, higher-ranking female sooty mangabeys (*Cercocebus torquatus atys*) have a higher foraging efficiency than lower-ranking females (Range and Noë 2002). In capuchins (*Cebus apella* and *Cebus capucinus*) and Japanese macaques (*Macaca fuscata*), higher-ranking individuals have higher food and energy intake rates relative to lower-ranking individuals (Janson 1985; Saito 1996; Vogel 2005).

There are few studies that measure food site residence time using the movements of individuals. Comparable data in cercopithecines are only available thus far for vervets and patas monkeys, both of which are more terrestrial than gray-cheeked mangabeys. Mean food site residence time of female mangabeys (66 s) was more than twice that of vervets in Laikipia, Kenya (approximately 25 s), and four times longer than that of patas monkeys, also in Laikipia (approximately 15 s; L.A. Isbell, unpublished data). Vervets in Laikipia feed mainly on small fruits, leaves, flowers, and gum whereas patas monkeys feed mainly on gums and arthropods; neither species eats bark (Isbell 1998; Isbell et al. 1998). These data suggest that the foods of mangabeys have longer site residence times than those of both vervets and patas monkeys. The rate of agonism between female mangabeys is also higher (Fig. 4) which may be due to differences in food types consumed.

In summary, we found substantial support for basic socioecological theory, which predicts that social relationships of female animals are affected by ecological conditions of their foods, in gray-cheeked mangabeys, an arboreal forest-dwelling Old World monkey. Female gray-cheeked mangabeys engage in agonistic interactions more frequently over foods that are depleted slowly and this is associated with having clearly defined linear dominance hierarchies. Importantly, however, the critical food type was not fruit, which is the most frequently eaten, but bark, eaten far less but for much longer per site. The benefit of being a high-ranking female includes being able to feed longer at food sites that are more slowly depleted and to aggressively force lower-ranking females from foods with long site residence times because such foods are more usurpable and

likely more valuable. Therefore, higher-ranking females may be able to obtain more foods and expend less energy to obtain those foods, in the short run gaining a greater net benefit from holding their higher positions and, in the long run, translating this benefit into relatively more offspring. These results add to growing evidence from other studies that a critical characteristic of food underlying agonistic social relationships in female animals is the length of time spent at a food resource.

Acknowledgments The Leakey Foundation and the University of California, Davis Department of Anthropology provided funding for this study. In Uganda, we thank the Office of the President, the Uganda National Council for Science and Technology, the Uganda Wildlife Authority, and the Makerere University Biological Field Station for permission to conduct research in Kibale National Park. We also thank C. Chapman for logistical support in the field, W. Olupot for habituating the study groups, and R. Kaserengenyu, S. Katusabe, R. Sabiiti, and P. Irumba for assistance in the field. In addition, we are grateful to M. Grote for help with statistical analyses, to A. Marshall, A. Harcourt, and two anonymous reviewers for helpful comments on earlier drafts of this manuscript, and to the UC Davis students who helped digitize the data. This study complied with the current laws of Uganda.
